(Dated: November 17, 2023)

The Bottleneck Travelling Salesman Problem (BTSP) stands as an NP-Hard optimization problem, suggesting a lack of solutions in polynomial time. With a complexity of $(N-1)!$ for N cities, the need for a more efficient solution becomes evident. In response, we propose the development of an algorithm rooted in quantum phase estimation and Grover's algorithm, aiming to provide a solution within the improved time frame of $\sqrt{(N-1)!}$. To validate the efficacy of our proposed quantum algorithm, testing will be conducted on simulators and potentially real quantum hardware. Subsequent to the experimental phase and implementation of enhancements, we will present our findings and insights gained. The research does not just aim to offer a quantum-powered solution to the BTSP but also adds to the conversation about how quantum algorithms can change how we solve tough optimization problems.

PACS numbers:

I. MOTIVATION

Continuous advancements in quantum computing have allowed for contemporary approaches to solve complex computational problems that were previously considered intractable using classical methods. Well known examples of these advancements include Shor's [1] and Grover's [2] algorithms for factoring and unstructured search respectively. The Bottleneck Traveling Salesman Problem (BTSP) serves as a challenging optimization problem in the field of logistics and operations research. Its practical applications range from optimizing vehicle routes, to circuit design. Consequently, the achievement of an efficient solution is highly sought after. However, the BTSP is classified as an NP-hard problem, indicating it is at least as difficult as the hardest problems in the NP class. For reference, an NP problem must satisfy two conditions: no known solution in polynomial time, and the verification of a solution in polynomial time. An NP-hard problem does not need to satisfy the verification condition. To address this problem, many heuristic approaches are explored [3][4]. However, inherent to such methods is a trade-off between precision and efficiency.

We embark on a journey at the intersection of quantum computing and optimization by introducing a quantum algorithm tailored to address the BTSP. It requires finding the shortest closed tour through a set of cities while minimizing the largest cost, the "bottleneck", along any route. Its computational complexity grows exponentially with the number of cities, rendering classical solutions impractical for large-scale instances. Our approach is to capitalize on the inherent quantum parallelism, as well as the unique feature of phase encoding in quantum computing. By exploiting these phenomena, we aim to encode and manipulate the costs associated with various routes

efficiently. Additionally, the utilization of Grover's search algorithm as a central component of our quantum approach significantly expedites the search for the optimal solution. Quantum searching, in general, may be useful for expediting the obtainment of solutions for problems belonging to the complexity class NP [5]. In this proposal, our primary objective is to highlight the theoretical foundation of the quantum algorithm and to discuss its potential computational advantages over classical methods. In conducting the research, we aim to work towards a clear understanding of these aspects. The following sections will detail the BTSP, Grover's algorithm, quantum phase estimation and their respective significance and complexity.

II. THEORY

A. Bottleneck Travelling Salesman Problem

FIG. 1: An undirected weighted graph representation of a symmetric 4-city system. The vertices represent cities and the edge weights represent the cost of travel.

*Electronic address: raveel@student.ubc.ca

The BTSP can be represented as a graph problem. We

start with a graph, whose vertices are labelled A through D, representing a 4-city system. We define movement from one vertex to another as a walk, done through the edges connecting our vertices. We are interested in a particular walk known as a Hamiltonian cycle that contains every vertex exactly once before returning to the start. Our graph also includes edge weights, we define as γ_i . The BTSP is to find the Hamiltonian cycle in a graph, where the largest edge weight (bottleneck) is minimized. This is distinct from the Travelling Salesman Problem (TSP) where the combined edge weights in a given cycle is minimized. The total possible Hamiltonian cycles is given by $(N-1)!$, where N is the number of nodes. We present a symmetric case in FIG. 1, $N_k \rightarrow N_{k+1} = N_{k+1} \rightarrow N_k = \gamma_i$. Thus the total possible cycles is $(N-1)!/2$. It is important to note that a solution to either BTSP or TSP is not unique. Moreover, BTSP solutions do not necessarily equate to the TSP solutions. We can illustrate an example below. Consider all the Hamiltonian cycles for a symmetric 4-city system:

$$\begin{aligned} A &\rightarrow B \rightarrow C \rightarrow D \rightarrow A \\ A &\rightarrow B \rightarrow D \rightarrow C \rightarrow A \\ A &\rightarrow C \rightarrow B \rightarrow D \rightarrow A \end{aligned}$$

Assigning some arbitrary weights, we can see the total costs of the cycles below. The first cycle is the solution to the BTSP as its largest edge weight at 5 is the smallest among all three. The last cycle is a solution to the TSP as its combined edge weight is the smallest.

$$\begin{aligned} \gamma_1 + \gamma_4 + \gamma_5 + \gamma_3 &= 4 + 4 + 5 + 4 = 17 \\ \gamma_1 + \gamma_6 + \gamma_5 + \gamma_2 &= 4 + 6 + 5 + 2 = 17 \\ \gamma_2 + \gamma_4 + \gamma_6 + \gamma_3 &= 2 + 4 + 6 + 4 = 16 \end{aligned}$$

By simply changing the weight of γ_6 to 5, we can illustrate that all cycles are solutions to the BTSP.

$$\begin{aligned} \gamma_1 + \gamma_4 + \gamma_5 + \gamma_3 &= 4 + 4 + 5 + 4 = 17 \\ \gamma_1 + \gamma_6 + \gamma_5 + \gamma_2 &= 4 + 5 + 5 + 2 = 16 \\ \gamma_2 + \gamma_4 + \gamma_6 + \gamma_3 &= 2 + 4 + 5 + 4 = 15 \end{aligned}$$

The computational complexity of the BTSP is known to be NP-hard, implying there is no algorithm for a solution in polynomial time. A brute-force approach would imply that we can run an algorithm in $\mathcal{O}((N-1)!)$ time.

B. Grover's Search Algorithm

In 1996, Lov Grover proposed a quantum algorithm for unstructured database search, where an N sized list could be searched in \sqrt{N} time [2]. This speed up can be realized for sufficiently large databases, but does not provide the exponential speedup promised by other quantum algorithms such as Shor's [1]. We can refer to FIG. 2 to see the quantum circuit representation. We will use the geometric representation of the algorithm shown in FIG. 3 to aid our understanding of the algorithm.

FIG. 2: A concise quantum circuit representation of Grover's search algorithm applied to an n -qubit system. The Hadamard $H^{\otimes n}$ gate creates a uniform superposition over all possible states N (2^n). The U_w gate marks our goal state. The U_s gate amplifies the amplitude of our goal state. the r exponent, refers to the number of iterations needed to maximize the amplitude. The approximate number is \sqrt{N} times.

Let us walk through one iteration of Grover's algorithm. Most quantum circuits are initialized at $|0\rangle$, then we apply the H gate, resulting in a uniform superposition:

$$|s\rangle = H^{\otimes n}|0^{\otimes n}\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \{0,1\}^n} |x\rangle \quad (1)$$

The orthogonal states to our goal state can be represented as the sum of all states not containing $|w\rangle$:

$$|w_{\perp}\rangle = \frac{1}{\sqrt{2^n - 1}} \sum_{x \in \{0,1\}^n, x \neq w} |x\rangle$$

From here we apply the U_w gate, for our reflection over the orthogonal states. This can be thought of flipping the sign on state $|w\rangle$ contained within $|s\rangle$. We can see the visual representation in FIG. 3.

FIG. 3: Geometric representation of Grover's algorithm. a) An iteration performed on an n -qubit system. Starting from the uniform superposition $|s\rangle$, we perform a reflection over the orthogonal states of $|w\rangle$ with U_w . Then we perform a reflection over the superposition state $|s\rangle$ with U_s . we can see our new state $|x\rangle = U_s U_w |s\rangle$ is closer to the goal state $|w\rangle$. A new iteration would imply reflecting again over $|w_{\perp}\rangle$ and then reflecting back over $|x\rangle$. b) An iteration performed on a 2-qubit system. Only one iteration is required to hit any goal state $|w\rangle$.

We then perform a similar reflection over the original state $|s\rangle$:

$$U_w|s\rangle = (\mathbb{I} - 2|w\rangle\langle w|)|s\rangle = |s'\rangle$$

$$U_s|s'\rangle = (2|s\rangle\langle s| - \mathbb{I})|s'\rangle = |s''\rangle$$

Our $|s''\rangle$ is now closer to our goal state $|w\rangle$. If we want to maximize our probability of measuring $|w\rangle$, we will need to perform a number of iterations (r). For a sufficiently large number of states, $N = 2^n$, we can make a few approximations to calculate r .

$$\langle w|s\rangle = \frac{1}{\sqrt{N}} = \sin \frac{\theta}{2} \approx \frac{\theta}{2} \quad (2)$$

$$P(w) = |\langle w|s\rangle|^2 = \frac{1}{N} = \sin^2 \frac{\theta}{2}$$

$$P(w) = |\langle w|(U_s U_w)^r|s\rangle|^2 = \frac{1}{N} = \sin^2 \left(\theta \left(\frac{1}{2} + r \right) \right)$$

To maximize the probability we need $P(w) = 1$, so we can set the inside of the sine function to $\pi/2$:

$$\theta \left(\frac{1}{2} + r \right) = \frac{\pi}{2}$$

$$r = \frac{\pi}{2\theta} + \frac{1}{2} \approx \frac{\pi}{2\theta} \quad (3)$$

Using (2) to substitute θ in eqn. 3, we can get an approximate result for r :

$$r \approx \frac{\pi}{4} \sqrt{N} \quad (4)$$

C. Quantum Phase Estimation Algorithm

The phase estimation algorithm initially proposed by Alexey Kitaev [6] plays an important role as a subroutine for the more widely known factoring algorithm by Peter Shor [1]. We first must briefly discuss the Quantum Fourier Transform (QFT) as it is key to understanding phase estimation [5]. Given a computational basis state $|x\rangle$, applying the QFT (F_N) results in:

$$F_N|x\rangle = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} e^{2\pi i x k N^{-1}} |k\rangle$$

Let us represent this in binary notation and decompose it into a tensor product. We can represent $|x\rangle$ as a string of bits, and the QFT as a tensor product of single qubit basis states:

$$|x\rangle = |x_1 x_2 \dots x_n\rangle = |x_1\rangle \otimes |x_2\rangle \otimes \dots \otimes |x_n\rangle$$

$$F_N|x\rangle = \frac{1}{\sqrt{2^n}} \bigotimes_{j=1}^n (|0\rangle + e^{2\pi i x k 2^{-j}} |1\rangle) \quad (5)$$

$$= \frac{1}{\sqrt{2^n}} ((|0\rangle + \omega_1 |1\rangle) \otimes (|0\rangle + \omega_2 |1\rangle) \otimes \dots \otimes (|0\rangle + \omega_n |1\rangle))$$

$$\begin{aligned} \omega_1 &= e^{2\pi i x 2^{-1}} = e^{2\pi i (0.x_n)} \\ \omega_2 &= e^{2\pi i x 2^{-2}} = e^{2\pi i (0.x_{n-1} x_n)} \\ &\dots \\ \omega_n &= e^{2\pi i x 2^{-n}} = e^{2\pi i (0.x_1 \dots x_n)} \end{aligned}$$

An important characteristic of the w_j is the bit shift occurring in the exponent. If we look at w_1 , the exponent has a factor $x 2^{-1}$, which is equivalent to one right bit shift: $x_1 \dots x_{n-1} . x_n$. Integer multiples of the exponent would imply full rotations returning to the same point. Thus we can ignore all the values on the left of the decimal and what remains is $0.x_n$.

Let us discuss the phase estimation problem. Given an eigenstate $|\lambda\rangle$ of a unitary operator U , we want to calculate a good approximation for $\phi \in [0, 1)$ satisfying:

$$U|\lambda\rangle = e^{2\pi i \phi} |\lambda\rangle \quad (6)$$

The phase estimation algorithm uses two registers of qubits. The first one will be a set of n control qubits that determine the precision of our approximation. The second register will be a set of m qubits initialized to an eigenstate $|\lambda\rangle$.

Let us walk through the quantum circuit in FIG. 4, to understand the inner workings of this algorithm. Our initialized state is $|0^{\otimes n} \lambda\rangle$. From here we perform the same operation we find in (1), where all the qubits in the first register are set to a uniform superposition on all states 2^n . The next portion of the algorithm involves applying controlled gates based on the unitary operator U . The function of these CU gates is to apply the operator U on $|\lambda\rangle$ if the control qubit is in the state $|1\rangle$. We can have a look at the effect on the n^{th} qubit, after it has been prepared in a superposition by the Hadamard gate:

$$\frac{1}{\sqrt{2}} (|0\rangle + |1\rangle) \otimes |\lambda\rangle = |0\lambda\rangle + |1\lambda\rangle$$

Applying CU and factoring out the eigenstate:

$$\begin{aligned} CU \frac{1}{\sqrt{2}} (|0\lambda\rangle + |1\lambda\rangle) &= \frac{1}{\sqrt{2}} (CU|0\lambda\rangle + CU|1\lambda\rangle) \\ &= \frac{1}{\sqrt{2}} (|0\lambda\rangle + e^{2\pi i \phi} |1\lambda\rangle) \\ &= \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i \phi} |1\rangle) \otimes |\lambda\rangle \end{aligned}$$

FIG. 4: A quantum circuit representation of the phase estimation algorithm. Given $U|\lambda\rangle = e^{2\pi i\phi}|\lambda\rangle$, this algorithm allows us to generate an approximation for $\phi \in [0, 1)$. The circuit consists of two registers of qubits. The first n -qubits are initialized to $|0\rangle$ and contribute to the precision of the ϕ value obtained. The second register of m -qubits is initialized to the eigenstate of U . The Hadamard gates, H , are used to create a uniform superposition in the first register. The control gates based on U are responsible for encoding phase to the qubits in the first register. Finally, a QFT^\dagger is performed on the first register to extract the encoded phase. Each subsequent qubit in the first register would require double the control gates. Thus, with a large n we obtain a more precise value for ϕ , but also exponentially increase our computation time.

We can see that the eigenstate after the CU operation is left unchanged. The phase has been encoded into the control qubit instead, a result that is due to the phase kickback. Thus, we can reuse our eigenstate for the next qubit. Consecutive qubits have double the number of CU operators as the previous, thus squaring the eigenvalue each time:

$$\begin{aligned} \text{qubit}_{n-1} &: |0\rangle + e^{2\pi i\phi^2}|1\rangle \\ &\dots \\ \text{qubit}_1 &: |0\rangle + e^{2\pi i\phi^{2^n}}|1\rangle \end{aligned}$$

We know that the value of $\phi < 1$. We can represent this in binary notation in the form $0.\phi_1\phi_2\dots\phi_n$:

$$\phi = \sum_{j=1}^n \phi_j 2^{-j}$$

If we have another look at the control qubits using binary notation for ϕ instead, we can see the result of the multiple CU operations simply results in right bit shifts:

$$\begin{aligned} \text{qubit}_n &: |0\rangle + e^{2\pi i(0.\phi_1\phi_2\dots\phi_n)}|1\rangle \\ \text{qubit}_{n-1} &: |0\rangle + e^{2\pi i(0.\phi_2\dots\phi_n)}|1\rangle \\ &\dots \\ \text{qubit}_1 &: |0\rangle + e^{2\pi i(0.\phi_n)}|1\rangle \end{aligned}$$

If we look at the form of the first register after all the CU operations in the state $|\alpha\rangle$, it will resemble the result of performing the QFT we saw in equation 5. Here, our ω_j are:

$$\begin{aligned} \omega_1 &= e^{2\pi i x 2^{-1}} = e^{2\pi i(0.\phi_n)} \\ \omega_2 &= e^{2\pi i x 2^{-2}} = e^{2\pi i(0.\phi_{n-1}\phi_n)} \\ &\dots \\ \omega_n &= e^{2\pi i x 2^{-n}} = e^{2\pi i(0.\phi_1\dots\phi_n)} \end{aligned}$$

Simply performing the inverse QFT will give us $|\phi\rangle = |\phi_1\phi_2\dots\phi_n\rangle$. We can immediately see the approximation is limited by the number of qubits in the first register. A simple strategy would be to increase the number of qubits; however this would also increase the computational cost as we double our use of CU gates for each additional qubit.

III. DETAILS OF PROPOSED EXPERIMENT/CALCULATION

Using the tools we explore in the theory section, we propose the creation of a quantum algorithm that will calculate a solution for the BTSP in $\mathcal{O}(\sqrt{(N-1)!})$. Solving the BTSP can be broken down into two steps:

1. Finding all Hamiltonian cycles.
2. Comparing the maximum edge weight contributions and finding a minimum.

There is a strategy for finding the Hamiltonian cycles through the phase estimation algorithm [7]. This strategy stores edge weights as phases and creates an N^N size diagonal matrix in which $(N-1)!$ entries correspond to the Hamiltonian cycles. This approach is feasible; however, it is not simple to distinguish each edge weight contribution in the cycle. For the BTSP we need to see the max edge weight contribution, thus we hope to leverage their approach and construct a strategy to find it in each Hamiltonian cycle.

Once all the max edge weights are available, the following challenge is to use Grover's algorithm in order to find the minimum. We need to construct a U_w . Given a function $f: \{0, 1, \dots, N-1\} \rightarrow \{0, 1\}$:

$$U_w|x\rangle = (-1)^{f(x)}|x\rangle = \begin{cases} -|x\rangle & \text{for } x = w \\ |x\rangle & \text{for } x \neq w \end{cases} \quad (7)$$

Here, we need to map our minimum edge weights to the inputs of our function f and devise a strategy where the minimum edge weight input would output a value of 1. If both steps are accomplished, we will have ourselves a quantum algorithm for the BTSP. We can then test this algorithm on open-source quantum simulators

or possibly use IBM Quantum Experience (limited free access). We can test the efficiency, errors, and drawbacks of our algorithm in the process. We can then implement improvements and test again.

IV. PLANNED SCHEDULE

Timeline	Plan
October - January	Research and Algorithm Construction
January - February	Algorithm Testing and Improvements
March	Thesis Writing

V. ACKNOWLEDGEMENTS

I want to express my gratitude to Dr. Matthew Chop-tuik for not only his supervision but also for the encouragement and support to pursue a topic that truly captivates my interest.

VI. APPENDIX: QUANTUM COMPUTING BASICS

A. Frequently Used Notation

Single qubit states:

$$|0\rangle = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, |1\rangle = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

2-qubit states:

$$|00\rangle = |0\rangle \otimes |0\rangle = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}, |01\rangle = |0\rangle \otimes |1\rangle = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}$$

$$|10\rangle = |1\rangle \otimes |0\rangle = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}, |11\rangle = |1\rangle \otimes |1\rangle = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}$$

Multiple qubit states are achieved through tensor products of single states. An n -qubit system will span a Hilbert space of dimension $N = 2^n$. We can see with the 2-qubit system that we have 4 states. Quantum logic gates serve as the quantum computing counterparts to

classical logic gates, performing operations on qubits instead of classical bits. Represented as unitary matrices, these operations must be reversible. Below we can see the Hadamard gate and the result of its application to single qubit states, frequently employed to establish a uniform superposition.

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

$$H|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) = |+\rangle$$

$$H|1\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) = |-\rangle$$

We can refer to equation 1 to see the result of Hadamard on an n -qubit system. Let us have a look at the Hadamard gate applied to $|00\rangle$:

$$\begin{aligned} H^{\otimes 2}|00\rangle &= H|0\rangle H|0\rangle \\ &= |+\rangle|+\rangle \\ &= \left(\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\right)\left(\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\right) \\ &= \frac{1}{2}(|0\rangle + |1\rangle)(|0\rangle + |1\rangle) \\ &= \frac{1}{2}(|00\rangle + |01\rangle + |10\rangle + |11\rangle) \end{aligned}$$

Here, we can see why Dirac notation is powerful as it simplifies tensor products and removes the need for matrix representation.
